

## MILLIMETER WAVE IMAGING SYSTEM

The present invention is a continuation in part of US patent application Serial No. 09/965,875, filed September 29, 2001 and Serial No. 10/639,322 filed August 12, 2003, both  
5 of which are incorporated by reference herein. The present invention relates to imaging systems and in particular to millimeter wave imaging systems.

### BACKGROUND OF THE INVENTION

10 Imaging systems operating at millimeter wavelengths (1cm to 1mm; 30 GHz to 300 GHz) are well known. These systems can be important because light at these wavelengths is not completely attenuated by substantial distances of fog or smoke, as is visible light. Light at millimeter wavelengths will also penetrate clothing and significant thickness of materials such as dry wood and wallboard. These millimeter wave imaging systems have therefore  
15 been proposed for aircraft to improve visibility through fog and for security applications for detection of hidden weapons and the like. Such systems are described in US Patents 5,121,124 and 5,365,237 that are assigned to Applicant's employer. The systems described in those patents utilize antennas in which the direction of collected millimeter wave radiation is a function of frequency. This type of antenna is referred to as a "frequency scanned"  
20 antenna. The collected millimeter wave light is analyzed in a spectrum analyzer to produce a one-dimensional image. Two dimensional images may be obtained by scanning. In the systems described in the '124 patent the antenna signal is used to modulate an acousto-optic device (a Bragg cell) that in turn modulates a laser beam to produce a spectral image. In the systems described in the '237 patent an electro-optic module is modulated by the antenna  
25 signal and the electro-optic module in turn modulates the laser beam to impose the millimeter wave spectral information on a laser beam that then is separated into spectral components by an etalon to produce an image.

US Patent No. 4,654,666 describes an imaging system which includes a frequency scanning  
30 antenna and a spectrum analyzer for converting coded radiation distributions collected by the antenna into a time coded distribution so that a one-dimensional scene can be reproduced.

The systems referred to above are complicated and costly to construct. What is needed is a relatively low cost, easy to operate millimeter wave imaging system, especially for use in portal screening for contraband.

5

## SUMMARY OF THE INVENTION

The present invention provides a millimeter wave imaging system that includes at least one millimeter wave frequency scanning antenna for collecting frequency dependent beams of millimeter wave radiation from a narrow one-dimensional field of view. The collected radiation is amplified at the collected frequencies and the amplified signals are separated into frequency dependent bins with a tapped-delay beam-former. These bins are then sampled to produce a one-dimensional image of the antenna field of view. A two dimensional image of a target may be obtained by moving the target across the field of view of the scanning antenna or by moving the antenna in order to scan its line of focus over the target.

In a first preferred embodiment the antenna is only 4.5 inches in length and constructed from WR-10 waveguide with inclined slots cut in one of the narrow walls at 79 mil spacings. This geometry creates a frequency-scanned antenna spanning a 20 degree vertical field of view over a 75.5-93.5 GHz operational band of the sensor, starting at approximately 1 degree below horizontal at 93.5 GHz and ranging to approximately 21 degrees below horizontal at 75.5 GHz. In this embodiment 64 of these antenna elements are arranged in four stacks of 16 antennas to construct a portal contraband screener. A narrow, rod-shaped cylindrical lens covers the waveguide slots at each element and vertically focuses the antenna beam 18 inches from the antenna. The antenna segments are aligned along one focal axis of a vertically oriented elliptical cylinder reflector, 4.5 inches across with the second, parallel focal axis of the reflector located 18 inches from the antenna. This arrangement gives a 2-dimensional beam focus at 18 inches, with an approximate depth of focus covering 14 inches at minimum range to about 29 inches at maximum range. The frequency-scan angular range corresponds to about 4.5 vertical inches at the minimum operational range of 14 inches. The horizontal and vertical resolution (half-power beam-width) at the center-band frequency of 84.5 GHz is

about 1.57 degrees, or less than ½-inch at the 18-inch focus. Each of the four stacks of antennas is directed at regions of a portal to permit composite front, side and back millimeter wave imaging of persons passing through the portal. The fixed antenna elements provide the vertical scan and the passage of the person provides the horizontal scan.

5

In a second preferred embodiment, the receiving element of the antenna is 0.6 meter in length constructed from a WR-10 slotted waveguide and a narrow, rod-shaped cylindrical lens positioned in front of the waveguide slotted wall. Inclined slots are cut in one of the narrow walls of the waveguide at 2 millimeters spacing. This geometry creates a frequency-scanned antenna spanning 20 degrees in one dimensional field of view over a 75.5-93.5 GHz operational band of the receiver, starting at approximately 1 degree below the normal to the waveguide axis at 93.5 GHz and ranging to approximately 21 degrees below normal at 75.5 GHz. The waveguide is aligned along the short focal axis of a vertically oriented elliptical cylinder reflector having short focal length of 0.4 meter and long focal length of 5 meters.

10

This antenna geometry provides approximately 25 millimeters (about 1 inch) horizontal and vertical spatial resolution at 5 meters from the apex of the reflector. Reflector is tilted back by 10 degrees such that frequency scanned angle (i.e. 20 degrees) of the beam varies within ±10 degrees with respect to horizontal. The antenna including receiving element and the reflector is mechanically scanned in the direction perpendicular to the reflector axis. Vertical frequency-scan of the beam and horizontal rotation of the antenna produces a two dimensional raster image. The depth of field for resolution to about 500 mm (twenty inches) is from 4.75 meters to 5.25 meters.

15

20

## BRIEF DESCRIPTION OF THE DRAWINGS

25

FIGS. 1A–1C show features of a one-dimensional frequency scanning slot antenna.

FIGS. 2A and 2B show techniques for focusing the antenna shown in FIGS. 1A – C.

FIGS. 3A and 3B show an arrangement 64 of the above antennas in a portal contraband scanner.

30

FIGS. 4 shows electronic circuits for converting millimeter wave signals to images.

FIG. 5 shows a person passing through a screening portal.

FIG. 6 shows an embodiment with a large depth of field.

FIGS. 7A and 7B show the relationship between resolution and distance between antenna and target.

FIGS. 8A and 8B show features of a second preferred embodiment of the present invention.

5 FIG. 9 is a chart of antenna patterns for the second preferred embodiment.

FIGS. 10A and 10B shows techniques for focusing the antenna of the second preferred embodiment.

FIG. 11 is a block diagram describing the major elements \_\_\_\_\_ of the second preferred embodiment.

10 FIG. 12 is a drawing of the beam former for the second preferred embodiment.

FIG. 13 shows experimental data from a prototype of the second preferred embodiment.

FIG. 14A is a drawing showing features of the prototype of the second preferred embodiment.

FIG. 14B is a drawing showing a preferred application of the second preferred embodiment.

15 FIG. 15A–15C show sample images taken with a prototype according to the second preferred embodiment.

## DETAILED DESCRIPTION OF PREFERRED EMBODIMENTS

### 20 FIRST PREFERRED EMBODIMENT

#### Antenna Element

FIGS 1A, 1B and 1C are drawings showing features of a one-dimensional millimeter wave antenna according to aspects of the present invention. FIG. 1A shows the elevation field of view of the basic antenna element 2. Each antenna element 2 is constructed of WR-10 waveguide has exterior dimensions  $a = 0.180''$ ,  $b = 0.130''$  and interior dimensions  $a =$   
25  $0.100''$ ,  $b = 0.050''$ . In fabrication of the antenna, one of the narrow walls is thinned from 40 mils to 6 mils. Then, each WR-10 waveguide antenna has 57 inclined slots 4 cut into its narrow wall at a spacing of  $0.079''$ , which serve as emitting elements. The angle of the slots, and thus the coupling coefficient, increases from 9.66 degrees on the feed end to over 25  
30 degrees at the load end to provide nearly constant field strength along the antenna length. The direction of the angle alternates, providing a “pi” phase shift between successive

coupling slots. This geometry creates for a vertical mounted antenna a frequency scan spanning a 20-degree vertical field of view over a 75.5 to 93.5 GHz operational band of the sensor starting at minus 1 degree with the horizontal at 93.5 GHz and ranging to approximately 21 degrees below the horizontal below the horizontal.

5

### **Focusing the Antenna Element**

In preferred embodiments the antenna element 2 shown in FIGS. 1A, 1B and 1C is focused to 18 inches as shown in FIGS. 2A and 2B. In this case a vertically oriented elliptical cylindrical mirror 8, 4.5 inches across has one of its focal lines at the center of slots 4 of antenna element 2 and its second focus at 18 inches from the antenna as shown in FIG. 2A. This focuses the antenna beam 8 in the horizontal direction at 18 inches. Also a narrow rod-shaped collimating lens 6 covers waveguide slots 4 and vertically focuses the antenna beam 8 at 18 inches from the antenna. At the frequency range of 93.5 to 73.5 GHz the wavelengths of the collected radiation are about 0.14 inch (3.6 mm) corresponding to the mid-frequency, 83.5 GHz. However, in this preferred embodiment the resolution element (as described in more detail below) is somewhat larger (in the range of about 0.5 inch) in both the horizontal and vertical directions. Antenna element 2 along with its focusing elements are designated as antenna element 50 in FIGS. 1A, 2B, 3A and 3B.

20

### **Antenna Electronics**

#### **Calibration and Amplification**

In this preferred embodiment Dicke switching is used for calibration of the imaging system. This technique utilizes, as shown in FIG.4 a front-end switch 20 that alternates between looking at the antenna signal and looking at a set temperature load 21. The front-end switch 20 switches at a rate of 3.84 kHz between the antenna and a load termination. The load can be heated by approximately 40K for one switching cycle. This allows the unit to perform a two-temperature calibration in real time, compensating for gain fluctuations in the amplifiers as well as temperature offsets. The switch itself is a W-band microwave monolithic integrated circuit (MMIC) PIN switch fabricated by M/A-Com with a transmission loss of 1.8 dB.

30

The front-end switch is packaged with, and feeds directly into, a front-end amplifier unit 22. This front-end amplifier unit consists of two low noise MMIC amplifiers 22A and 22B, band pass filter 22C and low noise MMIC output amplifier 22D. The amplifiers are required to have a wide bandwidth but maintain a low noise figure, as they set the noise temperature for the entire system. They operate over an 18 GHz bandwidth, from 75.5 GHz to 93.5 GHz. The first two amplifiers in the chain 22 A and 22B have a noise figure of approximately 4 dB over the 18 GHz band and a gain of about 19 dB. Band pass filter 22C separates these amplifiers from the third amplifier 22D that is of a slightly different design. The third amplifier 22D, the output amplifier, is tuned for a gain of about 22 dB and is capable of output powers of up to 1 mW before compressing. Once packaged, the entire gain stage has approximately 53 dB of gain and a noise output power of -11 dBm, with a noise figure averaging 7 dB. This includes losses from the filter and the transitions. Thus, each amplifier channel 22 provides 53 dB of gain, as well as an integrated matched load with a heater, and PIN switch for in-situ two-temperature flat field calibration. The MMIC amplifiers and the band pass filter are preferably fabricated using a co-planar waveguide design on an indium phosphide substrate.

#### Tapped Delay Beamformer

This broadband amplified antenna power is fed into a tapped-delay beamformer as shown in FIG. 4 for decomposition into frequency bins representing a vertical frequency image of the antenna field of view. Delay lines 26 transmit the amplified antenna signal into 32 signal ports of beamformer 24. Beginning at port 24-1 at the left side of beamformer 24, the signal to each port is delayed by 36 ps (relative to its left side neighbor port). The 36 ps delay is equivalent to three wavelengths at centerband of 83.5 GHz. (The millimeter wave frequency of 83 GHz corresponds to a wavelength of about 3.6 mm and light travels that far in about 12 ps.) Thus, a signal arriving at port 24-1 at time 0 would also arrive at port 24-2 at time 36 ps, would arrive at port 24-16 at time 576 ps and would arrive at port 24-32 at 1.152 ns. The series of 32 taps samples a total time interval of 1.152 nanoseconds, yielding a frequency resolution of 870 MHz for the beamformer. (The frequency resolution for these beamformers is the inverse of the total time spread; so in this case  $1/1.152 \text{ ns} = 870 \text{ MHz}$ .) The beamformer sorts the 18,000 MHz broadband signal from the antenna into 32 frequency bins

at an average separation of 580 MHz, thus over sampling the vertical focal plane by about 2.4X relative to the 1400 MHz bandwidth of each antenna beam. (The frequency separation is  $18,000\text{MHz}/31 = 580\text{ MHz}$ , and the beamwidth of the antenna beams is approximately equal to the inverse of the time [about 0.71 ns] for light to traverse the antenna element.)

5 Losses in the delay line, the beamforming lens, and input transition, as well as bandwidth splitting losses drop the power level at each lens output to about -36 dBm. A set of 32 sensitive detector diodes 30 integrates this power in the 32 frequency bins for each channel to provide a voltage signal corresponding to the intensity of the millimeter wave light collected by the antenna element at each of the 32 frequency ranges. The voltage signal from each of  
10 these diode signals is then read out by multiplexing readout integrated circuit chips on readout integrated circuit board 32.

The beamformer is implemented in a low loss dielectric, such as polypropylene, with smooth copper cladding. The delay lines 26 are created at very low cost with a lithographic etching  
15 that creates the circuit pattern, which is then sandwiched between two ground planes in a heated press. In preferred embodiments, the smoothness of the copper making up the inside surface of the delay lines is extremely important. Applicants have discovered that they could reduce the losses in these lines from 1.2 dB/inch to about 0.5 dB per inch by requiring that the copper surface roughness not exceed 300 nanometers. Prior art microwave surface  
20 roughness specifications were 1400 to 2900 nanometers. As explained above, the signals from these 32 taps are launched into beamforming lens 24, which steers the beam into one of 32 output ports 28 based upon the signal frequency.

### **Portal Contraband Screener**

25 In a preferred embodiment of the present invention shown in FIGS 3A and 3B 64 antenna elements of the type discussed above are utilized to provide a portal contraband screener. In this preferred embodiment four sets of 16 vertically stacked antenna elements 50 are arranged to monitor persons passing through a portal preferably on a horizontal escalator at a known velocity of about 1.5 feet per second. Each antenna element is 5 inches long so the  
30 stacks are 80 inches high with two of the stacks 10A and 10B arranged to view the person's

front and side and two of the stacks 10 C and 10 D arranged to view the person's side and rear all as shown in FIGS. 3A and 3B.

As a person 51 approaches the portal, which is about 41 inches wide; he/she enters the area of focus at a distance equal to roughly half the portal width (20.5 inches) from the portal centerline. At this range the forward-looking imaging antennas in stacks 10A and 10B are focused on the subject's front midline. As the person moves closer to the portal, the sensor foci sweep outward from the midline as indicated at 52 to generate a full 2-D image of the front and sides of the person. At the nominal travel speed of 1.5 feet per second, the antenna beam moves through one resolution element every 39.2 milliseconds. The imager reads out at 30 Hz, slightly over sampling the horizontal plane. In one second, as the person moves forward by 18 inches, the two antennas combine to record 60 columns of image pixels surrounding the front and two sides of the subject, separated horizontally by less than a quarter-inch projection. As the person leaves the portal, a second pair of antennas in stacks 10 C and 10 D images his/her back and sides in the same manner.

### **Electronic Features of the Contraband Screener**

In this embodiment, the 16 antenna elements making up each antenna column feed 16 receiver channels, which are configured into two 8-channel packages ("octapaks"). These octapaks include an amplifier set and beamformer for each antenna. The amplified signals from the antenna elements are processed as a pair of images, one representing the front and sides of the person and the other representing the sides and rear of the person passing through the portal. In this preferred embodiment the sensors operate at a 30 Hz rate, producing 30 images per second. If we set the passage so that the image time for both front and rear images take one second each, both front and rear images will each contain 60 pixels in the horizontal direction. For the vertical direction, each of the 16 antenna elements in each column produces 32 angular beams for a total of 512 angular beams. These beams will be equally spaced in the vertical direction over 80 inches only at about 14 inches from the antenna stacks and will overlap beyond about 14 inches. Thus, both the front and rear images will each contain about 60 pixels across and 512 pixels high, and the images will produce a wraparound view of the person traversing the portal. The pixel size is about 0.5 inch in the

horizontal direction and about 0.16 inch in the vertical direction at a range of 14 inches from the stacks. For those portions of the person located substantially farther from the antenna stacks than 14 inches, the pixel data should preferably be modified with computer software to accommodate the overlap to produce the wrap-around images.

5

Each of the two octopaks in each column holds eight switches and gain stages with WR-9 inputs. Each octopak includes connections for power and control signals and plenty of shielding to prevent feedback in the gain stage. Each octopak measures 1.5" long, 0.825" wide, and weighs 2.25 oz.

10

### **Background and Illumination**

15

When a person is not passing through the portal, the antenna arrays have nothing within their focal area and instead receive signal from a broad area beyond the focal region. This area can be coated with millimeter absorptive foam at ambient temperature. The foam acts as a blackbody at millimeter wave frequencies, emitting a fixed, broadband signal to the antennas. If the foam temperature is less than the temperature of a human body, the foam provides a good contrast to a person passing through the detector. This improves the clarity and sharpness of the generated images. Also, in preferred embodiments contour contrast can be added to the images of the persons being screened by providing a cold surface above the portal that would be a source of low temperature thermal radiation. Therefore, millimeter radiation in the band detected by the antenna elements that is reflected off the person after being emitted from the cold source will be very small compared to reflected radiation from other surrounding warmer sources. As a result the scanner will see substantial contrasts on the persons scanned depending on the angular orientation of various portions of his body, his clothing and potential contraband.

20

25

### **Privacy Issues**

30

A preferred application of the present invention as described above includes the visual examination beneath the clothing of people in search of weapons or other contraband. An example would be at an inspection portal at airports. This requires the examination of many innocent people. The images obtained show features of the persons warm skin. Body parts

normally covered with clothing are imaged with resolutions of about 0.5 inch. Therefore, privacy issues must be recognized and dealt with. In a preferred application of the portal contraband screener, two separate screeners are provided, one marked "women," and one marked "men." Inspection personnel for the women screener are female and inspection personnel for the men screener are male. The monitors showing images of the people being inspected are protected from public view and images that are saved for evidentiary purposes are carefully controlled by inspection personnel. Any person would have the right to not be screened by the contraband screeners but persons exercising that right would be subject to an appropriate manual search.

In another preferred embodiment, computer software would be provided to blur the images at the location of sensitive body parts. In another preferred embodiment, sophisticated software is provided which provides recognition of specific contraband such as guns, knives, and bombs. An alarm signal would then be provided if there is an indication of such contraband on the body of a subject so that the person could be selected for a more specific search. The software could also locate the suspected contraband by placing an appropriate logo on the subjects image at the position of the contraband.

## SECOND PREFERRED EMBODIMENT

### Single Stick Imager

In another embodiment of the invention is a low cost "single stick" imager. In this case, the unit has only one antenna which is generally as described above but in this specific case, the antenna is 26 inches long as compared to the 5-inch antennas used in the portal contraband screener.

FIGS 8A and 8B are drawings of a one-dimensional millimeter wave antenna element according to aspects of the present invention. FIG. 8A shows a front view of the antenna without lens CA which is shown in the FIG. 8B side view. Antenna element 1 is constructed from WR-10 waveguide with exterior dimensions  $a = 0.180"$ ,  $b = 0.130"$  and interior dimensions  $a = 0.100"$ ,  $b = 0.050"$ , slotted section of this antenna element is 24 inches long. In fabrication of the antenna, one of the narrow walls is thinned from 40 mils to 6 mils. Then

300 inclined slots 4A are cut into the narrow wall at a spacing of 2 mm, which serve as receiving apertures (this compares to 57 slots in the 5" antenna described above). The angle of the slots varies from 3.6 degrees at the input port 60 of the waveguide and gradually increases towards the terminated end 7 in order to provide nearly constant signal coupling along its length. The direction of the angle alternates, providing a 180 degrees phase shift between successive coupling slots. This geometry creates for a vertically mounted antenna a frequency scan spanning a 20-degree vertical field of view over a 75.5 to 93.5 GHz operational band of the system. In the vertical (elevation) plane the antenna receiver element produces a narrow 0.2 degree wide beams at each frequency as shown in FIG. 9. In horizontal plane its beam is 120 degrees wide due to small "b" dimension of the waveguide.

### **Focusing the Antenna Element**

In a preferred embodiments the antenna element 1 shown in FIGS. 10A is focused to 5 meters as shown in FIGS. 10A and 10B. In this case a vertically oriented elliptical cylindrical mirror 8, measuring 0.6 meter in width and 0.8 meters in height, has one of its focal lines located at the center of slots 5 of the receiver element 1 and its second focus 9 at 5 meters from the antenna as shown in FIG. 10A. This focuses the antenna beam 10 in the horizontal direction at 5 meters. A narrow rod-shaped lens 6A covers waveguide slots 4A and vertically focuses the antenna beam 11 corresponding to a frequency 93.5 GHz at 5 meters from the antenna into a focal spot 12. A lower frequency beam 13 of about 75.5 GHz is focused at the same distance from the antenna but into a different focal spot 14. Beam geometry shown in FIG. 10B assumes that the waveguide antenna signal is collected at the bottom port 6 of the slotted waveguide.

### **Antenna Electronics**

#### **Calibration and Amplification**

In this preferred embodiment Dicke switching is used for calibration of the imaging system. This technique utilizes, as shown in FIG.3, a front-end switch 20 that alternates between looking at the antenna 2A and looking at a set temperature load 21. The front-end switch 20 switches at a rate of 3.84 kHz. The load can be heated by approximately 40K for one

switching cycle. This allows the unit to perform a two-temperature calibration in real time, compensating for gain fluctuations in the amplifiers as well as temperature offsets. The switch itself is a W-band microwave monolithic integrated circuit (MMIC) PIN switch fabricated by M/A-Com with a transmission loss of 1.8 dB.

5

The Dicke switch 20 is packaged with a low noise amplifier 62 in a signal amplification unit 64. The amplifier 62 includes a series of low noise MMIC wide band amplifiers which provide output power in the 75.5-95.5 GHz frequency band sufficient to drive mm-wave detectors within tapped delay beam-former 66. The amplifiers are required to have a wide bandwidth but maintain a low noise figure, as they set the noise temperature for the entire system. They operate over an 18 GHz bandwidth, from 75.5 GHz to 93.5 GHz. with a noise figure approximately 7 dB. The MMIC amplifiers and other amplification unit components are preferably fabricated using a co-planer waveguide design on an indium phosphide substrate.

15

#### Tapped Delay Beamformer

Broadband antenna signal from antenna 2A is first amplified and then is fed into a tapped-delay beamformer 66 as shown in FIG. 11 and Fig. 12 for decomposition into frequency bins representing vertical image pixels of the antenna field of view. As shown in further detail in FIG. 12 the beam former includes an input line 68, a delay line network 70, a Rotman lens 72, horn arrays at the input 76 and output 78 of the lens. Signal lines connected to the output horns are terminated into mm-wave detector circuits 80 tuned to specific frequencies. Delay line network splits signal power among the input horns 76 and creates a constant time delay between signals radiated by adjacent horns into the Rotman lens. At the other end of the Rotman lens these signals combine constructively for a certain frequency at one of the 128 output horns 78 thus sorting mm-wave power into different output ports for different frequencies. Incremental signal delay between input horns is selected to achieve 300 MHz frequency resolution of the beamformer. This narrow band focusing capability of the beamformer has been accomplished and demonstrated experimentally by applicants as illustrated by FIG. 13. A narrow peak 32A seen in FIG. 13 represents response of one of the

30

128 output channels of the beamformer. Similar sharp responses have also been observed at each of the 128 output channels of the circuit for other frequencies.

The beamformer is implemented in a low loss dielectric, such as polypropylene, with smooth copper cladding. The delay lines 70 are created at very low cost with lithographic etching that creates the circuit pattern, which is then sandwiched between two ground planes in a heated press. In preferred embodiments, the smoothness of the copper making up the inside surface of the delay lines is extremely important as for the embodiment described above, applicants limit losses to about 0.5 dB per inch by requiring that the copper surface roughness not exceed 300 nanometers. Prior art microwave surface roughness specifications were 1400 to 2900 nanometers.

#### Signal detection and sampling

At a single input frequency the beamformer material is responsible for approximately 20dB signal loss according to the data in FIG. 13. For 18 GHz broadband input an additional 21dB signal loss due to input power splitting among 128 output channels would result in a total signal attenuation of at least 41dB per channel. This very low power is then detected by channel detectors 82 as shown in FIG. 12. The detector output voltage is amplified, integrated and digitized by readout chips 80. Very high sensitivity mm-wave detector diodes are used in the imager such as Sb-heterostructure diodes manufactured by HRL Laboratories LLC to insure that signal-to-noise performance of the imager is not degrading in the detector and readout circuitry.

Digitized signals for each of the 128 frequency channels are received by an interface module 35 shown in FIG. 11, which communicates with computer 36 where the data is finally processed and displayed into an image. The computer is also responsible for setting optimum performance parameter of the imager such as channel gains, integration time etc. The same computer is used to control horizontal scanning of the image using motorized rotation stage. A communication line 37 between computer and interface module 35 can be either wired or wireless depending on which method is more suitable for a particular application.

### Mechanically scanned imager for field deployment

- 5 In a preferred embodiment the above antenna system including mm-wave and low frequency signal processing electronics is integrated with mechanical rotation stage to produce a two dimensional raster image of an object in the focal plane of the antenna.

10 This preferred configuration of the imager is shown in FIG. 14. A mm-wave frequency-scanned antenna system 84 comprising a slotted- waveguide receiver 2A and reflector 8A is mounted on top of a computer controlled precision rotation stage 86. The base of the stage to which antenna is attached is rotated horizontally by a motor 88 in steps of 0.12 degree such that the focal spot at 5 meters from the imager shifts horizontally by approximately one half of the spot diameter per step. The stage is designed to be mechanically stable to ensure that  
15 the beam angular random walk does not exceed 0.05 degree in both horizontal and vertical directions. Rotation base and the motor drive are made part of a heavy duty tripod mount 91 for easy transportation and deployment. The stepper motor is powered by a motor control module 92 that receives instruction from a remote computer station 94. A mm-wave signal processing and sampling module 90 is attached to the same rotation stage as the antenna  
20 system. Image acquisition is controlled by an interface module 96 communicating with computer 94. Computer 94 is preferably a battery powered portable PC with a flat screen for image display. Computer characteristics have to be sufficient to perform imager control functions, signal acquisition, image processing and display in real time. Computer 94 communicates with the control and interface modules 92 and 96 remotely via a cable or a  
25 wireless link depending on application requirements. Connections between module 92 and motor 88, mm-wave module 90 and interface unit 96 are preferably wired.

An example of imager deployment is shown in FIG. 14B illustrating POW screening for a possibility of hidden weapons. An operator 98 controls imager 84 from a safe distance using  
30 a computer 100 whereas a POW subject 73 is ordered to stand in the focal plane of the imager. A full image of the subject is scanned within a few seconds and image is displayed

on the computer screen 72 for hidden weapons analysis. Multiple images of various aspects of subject can be taken sequentially if necessary.

A mechanically scanned image using current state of the art technology has been successfully built and tested by applicants. The imager provided approximately 3 Kelvin temperature resolution for an image size 128 vertical and 60 horizontal pixels and acquisition time of 2 seconds. It has been found that at this temperature resolution various metal objects such as guns, large knives and metal-pipe suicide vests can be detected by the system if subject is scanned in open space that allows the sky to be reflected from the surface of the metal. FIG. 15A shows examples of such scanned imaged for a subject wearing a simulated pipe suicide vest 104, FIG. 15B a metal knife 106 and FIG. 15C a hand gun 108.

#### Other Embodiments

Persons skilled in the art of contraband detection will recognize that many modifications can be made to the examples presented above. For example, instead of having the person pass through the portal on a horizontal escalator as described above, the person could be required to walk through the portal at a designated pace such as about  $\frac{1}{4}$  the normal walking speed. A millimeter wave transparent barrier 60 can be placed in the portal as shown in FIGS 5 and 6 in order to assure the proper positioning of the persons relative to the antenna elements. Various tradeoffs are possible in the selection of the focal position of the antenna elements. Positioning the antenna optically farther away from the persons being screened and increasing the focal length can provide greater depth of focus of the antenna elements. This can be done with mirrors 61 as shown in FIG. 6 to keep the unit compact. In FIG. 7 an estimate is provided of the approximate transverse resolution of the scanner as a function of distance of the between the surface being imaged and the antenna elements.

-----

While the present invention has been described above in terms of particular embodiments, persons skilled in the art will recognize that many other changes may be made. For example,

infrared or visible cameras synchronized with the millimeter wave screener may be adapted to provide correlated identity and reference information. Better resolution could be achieved by providing automatic focusing of the antenna elements. Alternatively, additional sets of elements could be provided with various focal lengths with processor software programmed to select the best focus for each portion of the target person as he/she passes through the portal. Increasing the size of the antenna could also improve the resolution. The person passing through the portal could be rotated before a single stack or they could be rotated before the four stacks. For applications where plenty of time is available a single element or fewer elements could be scanned across a person being screened, either automatically or by hand. Modifications to the amplifier shown in FIG. 4 could be made but preferably gains of at least 50 dB should be provided. The single stick imager shown in FIGS. 8A and 8B is positioned vertically and rotated horizontally. In other embodiments, these directions could be reviewed. The extent of rotation could be any amount from a few degrees for the application described above to a 360 degree complete rotation. Also, the single stick imager could be fixed in position and the subject being imaged could be moved laterally across the vertical beam. Also, the subject could be rotated in the vertical beam. Therefore, the scope of the present invention should be determined by the appended claims and their legal equivalents.
